PyEDA: Data Structures and Algorithms for Electronic Design Automation

Chris Drake‡*

https://www.youtube.com/watch?v=cljDuK0ouRs

Abstract—This paper introduces PyEDA, a Python library for electronic design automation (EDA). PyEDA provides both a high level interface to the representation of Boolean functions, and blazingly-fast C extensions for fundamental algorithms where performance is essential. PyEDA is a hobby project which has the simple but audacious goal of improving the state of digital design by using Python.

Introduction

Chip design and verification is a complicated undertaking. You must assemble a large team of engineers with many different specialties: front-end design entry, logic verification, power optimization, synthesis, place and route, physical verification, and so on. Unfortunately, the tools, languages, and work flows offered by the electronic design automation (EDA) industry are, in this author’s opinion, largely a pit of despair. The languages most familiar to chip design and verification engineers are Verilog (now SystemVerilog), C/C++, TCL, and Perl. Flows are patched together from several proprietary tools with incompatible data representations. Even with Python’s strength in scientific computing, it has largely failed to penetrate this space. In short, EDA needs more Python!

This paper surveys some of the features and applications of PyEDA, a Python library for electronic design automation. PyEDA provides both a high level interface to the representation of Boolean functions, and blazingly-fast C extensions for fundamental algorithms where performance is essential.

PyEDA is a hobby project, but in the past year it has seen some interesting adoption from University students. For example, students at Vanderbilt University used it to model system reliability [Nan14], and students at Saarland University used as part of a fast DQBF Refutation tool [Fin14].

Even though the name “PyEDA” implies that the library is specific to EDA, it is actually general in nature. Some of the techniques used for designing and verifying digital logic are fundamental to computer science. For example, we will discuss applications of Boolean satisfiability (SAT), the definitive NP-complete problem.

PyEDA’s repository is hosted at https://github.com/cjdrake/pyeda.git, and its documentation is hosted at http://pyeda.rtfd.org.

Note About Code Blocks

This document contains several Python code blocks. For the sake of simplicity, we assume you have PyEDA installed, and have prepared an interactive terminal by executing:

```python
>>> from pyeda.inter import *
```

Boolean Variables and Functions

At its core, PyEDA provides a powerful API for creating and manipulating Boolean functions.

First, let us provide the standard definitions.

A Boolean variable is an abstract numerical quantity that can take any value in the set \{0, 1\}. A Boolean function is a rule that maps points in an \(N\)-dimensional Boolean space to an element in \{0, 1\}. Formally, \(f : B^N \rightarrow B\), where \(B^N\) means the Cartesian product of \(N\) sets of type \{0, 1\}. For example, if you have three input variables, \(a, b, c\), each defined on \{0, 1\}, then \(B^3 = \{0, 1\}^3 = \{(0,0,0), (0,0,1), ... , (1,1,1)\}\). \(B^3\) is the domain of the function (the input part), and \(B = \{0, 1\}\) is the range of the function (the output part). The set of all input variables a function depends on is called its support.

There are several ways to represent a Boolean function, and different data structures have different tradeoffs. In the following sections, we will give a brief overview of PyEDA’s API for logic expressions, truth tables, and binary decision diagrams. In addition, we will provide implementation notes for several useful applications.

Logic Expressions

Logic expressions are a powerful and flexible way to represent Boolean functions. They are implemented as a graph, with atoms at the branches, and operators at the leaves. Atomic elements are literals (variables and complemented variables), and constants (zero and one). The supported algebraic operators are Not, Or, And, Xor, Equal, Implies, and ITE (if-then-else).

For general purpose use, symbolic logic expressions are PyEDA’s central data type. Since release 0.27, they have been implemented using a high performance C library.

Expressions are fast, and reasonably compact. On the other hand, they are generally not canonical, and determining expression equivalence is NP-complete. Conversion to a canonical expression form can result in exponential size.
Performing simplification can dramatically reduce the size and depth of your logic expressions.

**TABLE 1: Boolean OR/AND Identities**

<table>
<thead>
<tr>
<th>Construction</th>
</tr>
</thead>
<tbody>
<tr>
<td>To construct a logic expression, first start by defining some symbolic variables of type Expression:</td>
</tr>
<tr>
<td>&gt;&gt;&gt; a, b, c, d = map(exprvar, 'abcd')</td>
</tr>
</tbody>
</table>

By overloading Python’s logical operators, you can build expression algebraically:

>>> F = ~a | b & c ^ ~d

Use methods from the Function base class to explore the function’s basic properties:

>>> F.support
frozenset({a: 0, b: 1, c: 1, d: 0}, 1)

There are also several factory functions that offer more power than Python’s built-in binary operators. For example, operators such as Or, And, and Xor allow you to construct N-ary expressions:

>>> a ^ b ^ c
Xor(Xor(a, b), c)

Also, functions such as OneHot, and Majority implement powerful, higher order functions:

>>> OneHot(a, b, c)
And(Or(~a, ~b), Or(~a, ~c), Or(~a, b, c))

**Simplification**

The laws of Boolean Algebra can be used to simplify expressions. For example, Table 1 enumerates a partial list of Boolean identities for the Or and And operators.

Most laws are computationally easy to apply. PyEDA allows you to construct unsimplified Boolean expressions, and provides the simplify method to perform such inexpensive transformations.

For example:

>>> F = ~a | a
>>> F
Or(~a, a)

>>> F.simplify()
Or(~a, a)

>>> x = Xor(a, ~b, Xnor(~a, b), c)
>>> x
Xor(a, ~b, Xnor(~a, b), c)

Performing simplification can dramatically reduce the size and depth of your logic expressions.

**Transformation**

PyEDA also supports a growing list of expression transformations. Since expressions are not a canonical form, transformations can help explore tradeoffs in time and space, as well as convert an expression to a form suitable for a particular algorithm.

For example, in addition to the primary operators Not, Or, and And, expressions also natively support the secondary Xor, Equal, Implies, and ITE (if-then-else) operators. By transforming all secondary operators into primary operators, and pushing all Not operators down towards the leaf nodes, you arrive at what is known as "negation normal form".

>>> F = Xor(a >> b, c.eq(d))
>>> F.to_nnf()
And(Or(And(Or(c, d), Or(~c, ~d)), And(a, ~b)),
Or(~a, b, And(~c, ~d), And(c, d)))

Currently, expressions also support conversion to the following forms:

- Binary operator (only two args per Or, And, etc)
- Disjunctive Normal Form (DNF)
- Conjunctive Normal Form (CNF)

DNF and CNF expressions are "two-level" forms. That is, the entire expression is either an Or of And clauses (DNF), or an And of Or clauses (CNF). DNF expressions are also called "covers", and are important in both two-level and multi-level logic minimization. CNF expressions play an important role in satisfiability. We will briefly cover both of these topics in subsequent sections.

**Visualization**

Boolean expressions support a to_dot() method, which can be used to convert the graph structure to DOT format for consumption by Graphviz. For example, Figure 1 shows the Graphviz output on the majority function in three variables:

```python
>>> F = Majority(a, b, c)
>>> F.to_dot()
```

**The expr Function**

The expr function is a factory function that attempts to transform any input into a logic expression. It does the obvious thing when converting inputs that look like Boolean values:

```python
>>> expr(False)
0
>>> expr(1)
```
But it also implements a full top-down parser of expressions. For example:

```python
>>> expr("a | b ^ c & d")
Or(a, Xor(b, And(c, d)))
```

See the documentation for a complete list of supported operators accepted by the `expr` function.

### Boolean Satisfiability

One of the most interesting questions in computer science is whether a given Boolean function is satisfiable, or SAT. That is, for a given function \( F \), is there a set of input assignments that will produce an output of 1?

PyEDA Boolean functions implement two functions for this purpose, `satisfy_one` and `satisfy_all`. The former answers the question in a yes/no fashion, returning a satisfying input point if the function is satisfiable, and `None` otherwise. The latter returns a generator that will iterate through all satisfying input points.

SAT has all kinds of applications in both digital design and verification. In digital design, it can be used in equivalence checking, test pattern generation, model checking, formal verification, and constrained-random verification, among others. SAT finds its way into other areas as well. For example, modern package management systems such as apt and yum might use SAT to guarantee that certain dependencies are satisfied for a given configuration.

The `pyeda.boolalg.picosat` module provides an interface to the modern SAT solver PicoSAT [Bie08]. When a logic expression is in conjunctive normal form (CNF), calling the `satisfy_*` methods will invoke PicoSAT transparently.

For example:

```python
>>> F = OneHot(a, b, c)
>>> F.is_cnf()
True
>>> F.satisfy_one()
{a: 0, b: 0, c: 1}
```

When an expression is not a CNF, PyEDA will resort to a standard, backtracking algorithm. The worst-case performance of this implementation is exponential, but is acceptable for many real-world scenarios.

### Tseitin Transformation

The worst case memory consumption when converting to CNF is exponential. This is due to the fact that distribution of \( M \) \( \lor \) clauses over \( N \) \( \land \) clauses (or vice-versa) requires \( M \times N \) clauses.

```python
>>> Or(And(a, b), And(c, d)).to_cnf()
And(Or(a, c), Or(b, c), Or(a, d), Or(b, d))
```

Logic expressions support the `tseitin` method, which performs Tseitin’s transformation on the input expression. For more information about this transformation, see [Tse68].

The Tseitin transformation does not produce an equivalent expression, but rather an equisatisfiable CNF, with the addition of auxiliary variables. The important feature is that it can convert any expression into a CNF, which can be solved using PicoSAT.

```python
>>> F = Xor(a, b, c, d)
>>> soln = F.tseitin().satisfy_one()
>>> soln
{a: 0,
 aux[0]: 1,
 aux[1]: 1,
...
 b: 0,
 c: 0,
 d: 1}
```

You can safely discard the `aux` variables to get the solution:

```python
>>> {k: v for k, v in soln.items() if k.name != 'aux'}
{a: 0, b: 0, c: 0, d: 1}
```

### Truth Tables

The most straightforward way to represent a Boolean function is to simply enumerate all possible mappings from input assignment to output values. This is known as a truth table. It is implemented as a packed list, where the index of the output value corresponds to the assignment of the input variables. The nature of this data structure implies an exponential size. For \( N \) input variables, the table will be size \( 2^N \). It is therefore mostly useful for manual definition and inspection of functions of reasonable size.

To construct a truth table from scratch, use the `truthtable` factory function. For example, to represent the `And` function:

```python
>>> truthtable([a, b], [False, False, False, True])
# This also works
>>> truthtable([a, b], "0001")
```

You can also convert expressions to truth tables using the `expr2truthtable` function:

```python
>>> expr2truthtable(And(~x[0], ~x[1], x[2], ~x[3]))
   c b a
0  0  0 : 1
0  0  1 : 1
0  1  0 : 1
0  1  1 : 0
1  0  0 : 1
1  0  1 : 0
1  1  0 : 0
1  1  1 : 0
```

### Partial Definitions

Another use for truth tables is the representation of partially defined functions. Logic expressions and binary decision diagrams are completely defined, meaning that their implementation imposes a complete mapping from all points in the domain to \{0, 1\}. Truth tables allow you to specify some function outputs as "don’t care". You can accomplish this by using either "-" or "X" with the `truthtable` function.

For example, a seven segment display is used to display decimal numbers. The codes "0000" through "1001" are used for 0-9, but codes "1010" through "1111" are not important, and therefore can be labeled as "don’t care".

```python
>>> X = ttvars('x', 4)
>>> F1 = truthtable(X, "0000001111111111")
>>> F2 = truthtable(X, "0000111110000000")
```

To convert a table to a two-level, disjunctive normal form (DNF) expression, use the `truthtable2expr` function:

```python
>>> truthtable2expr(F1)
Or(And(x[0], ~x[1], x[2], ~x[3]),
   And(~x[0], x[1], x[2], ~x[3]),
   And(~x[0], x[1], x[2], ~x[3]),
   And(~x[0], ~x[1], ~x[2], x[3]),
   And(x[0], ~x[1], ~x[2], x[3]))
```
Two-Level Logic Minimization

When choosing a physical implementation for a Boolean function, the size of the logic network is proportional to its cost, in terms of area and power. Therefore it is desirable to reduce the size of that network.

Logic minimization of two-level forms is an NP-complete problem. It is equivalent to finding a minimal-cost set of subsets of a set $S$ that covers $S$. This is sometimes called the "paving problem", because it is conceptually similar to finding the cheapest configuration of tiles that cover a floor. Due to the complexity of this operation, PyEDA uses a C extension to the Berkeley Espresso library [Bra84].

After calling the `espresso_tts` function on the $F_1$ and $F_2$ truth tables from above, observe how much smaller (and therefore cheaper) the resulting DNF expression is:

```python
>>> F1M, F2M = espresso_tts(F1, F2)
>>> F1M
Or(x[3], And(x[0], x[2]), And(x[1], x[2]))
```

Binary Decision Diagrams

A binary decision diagram is a directed acyclic graph used to represent a Boolean function. They were originally introduced by Lee, and later by Akers. In 1986, Randal Bryant introduced the reduced, ordered BDD (ROBDD).

The ROBDD is a canonical form, which means that given an identical ordering of input variables, equivalent Boolean functions will always reduce to the same ROBDD. This is a desirable property for determining formal equivalence. Also, it means that unsatisfiable functions will be reduced to zero, making SAT/UNSAT calculations trivial. Due to these auspicious properties, the term BDD almost always refers to some minor variation of the ROBDD devised by Bryant.

The downside of BDDs is that certain functions, no matter how cleverly you order their input variables, will result in an exponentially-sized graph data structure.

Construction

Like logic expressions, you can construct a BDD by starting with symbolic variables and combining them with operators.

For example:

```python
>>> a, b, c = map(bddvar, 'abc')
>>> F = a & b & c
>>> F.support
frozenset({a, b, c})
>>> F.restrict({a: 1, b: 1})
0
>>> F & 0
0
```

The `expr2bdd` function can also be used to convert any expression into an equivalent BDD:

```python
>>> expr2bdd(expr("(s ? d1 : d0) <=> (s & d1 | ~s & d0)"))
```

Equivalence

As we mentioned before, BDDs are a canonical form. This makes checking for SAT, UNSAT, and formal equivalence trivial.

```python
>>> ~a & a
0
>>> ~a & ~b | ~a & b | a & ~b | a & b
1
>>> F = a ^ b
```

Future Directions for Function Data Structures

The implementation of Boolean functions is a vast field, and PyEDA is really only scratching the surface. In this section we will describe several directions for improvement.

Due to their fundamentally exponential size, truth tables have limited application. It is more common for tabular function representations to use an implicant table, sometimes referred to as a "cover". PyEDA has some support for implicant tables in the Espresso C extension, but this functionality is not exposed to the user interface.

PyEDA's BDD implementation uses a unique table, so $F$ and $G$ from the previous example are actually just two different names for the same object.

Visualization

Like expressions, binary decision diagrams also support a `to_dot()` method, which can be used to convert the graph structure to DOT format for consumption by Graphviz. For example, Figure 2 shows the Graphviz output on the majority function in three variables:

```python
>>> expr2bdd(expr("Majority(a, b, c)")).to_dot()
```

Fig. 2: Majority BDD rendered by Graphviz
There are several function representations left for consideration. Within the realm of decision diagrams, we have not considered algebraic decision diagrams (ADDS), or zero-suppressed decision diagrams (ZDDS). Within the realm of graph-based structures primarily for logic synthesis, we have not considered the and-inverter-graph (AIG), or the majority-inverter-graph (MIG).

Function Arrays
When dealing with several related Boolean functions, it is usually convenient to index the inputs and outputs. For this purpose, PyEDA includes a multi-dimensional array (MDA) data type, called a farray (function array).

The most pervasive example is computation involving any numeric data type. For example, let’s say you want to add two numbers A and B. If these numbers are 32-bit integers, there are 64 total inputs, not including a carry-in. The conventional way of labeling the input variables is \(a_0, a_1, \ldots, a_{31}\) and \(b_0, b_1, \ldots, b_{31}\).

Furthermore, you can extend the symbolic algebra of Boolean functions to arrays. For example, the element-wise XOR of A and B is also an array.

In this section, we will briefly discuss farray construction, slicing operations, and algebraic operators. Function arrays can be constructed using any Function implementation, but for simplicity we will restrict the discussion to logic expressions.

Construction
The farray constructor can be used to create an array of arbitrary expressions.

```python
>>> a, b, c, d = map(exprvar, 'abcd')
>>> F = farray([a, b, And(a, c), Or(b, d)])
```

As you can see, this produces a one-dimensional array of size 4.

The shape of the previous array uses Python’s conventional, exclusive indexing scheme in one dimension. The farray constructor also supports multi-dimensional arrays:

```python
>>> G = farray([
    [And(a, c), Or(b, d)],
    [Xor(b, c), Equal(c, d)]]
```

Algebraic Operations
Function arrays are algebraic data types, which support the following symbolic operators:

- unary reductions (uor, uand, uxor, ...)
- bitwise logic (~ | & ^)
- shifts (<< >>)
- concatenation (+)
- repetition (*)

Combining function and array operators allows us to implement a reasonably complete domain-specific language (DSL) for symbolic Boolean algebra in Python.

Consider, for example, the implementation of the xtime function, which is an integral part of the AES algorithm.

The Verilog implementation, as a function:

```verilog
function automatic logic [7:0] xtime(logic [7:0] b, int n);
  xtime = b;
  for (int i = 0; i < n; i++)
    xtime = {xtime[6:0], 1'b0} 
      ^ (8'h1b & {8{xtime[7]}});
endfunction
```

And the PyEDA implementation:

```python
def xtime(b, n):
  for i in range(n):
    b = (exprzeros(1) + b[:7]) 
    ^ uint2exprs(0x1b, 8) & b[7:8]
  return b
```
Practical Applications

Arrays of functions have many practical applications. For example, the `pyeda.logic.addition` module contains implementations of ripple-carry, brent-kung, and kogge-stone addition logic. Here is the digital logic implementation of \(2 + 2 = 4\):

```python
>>> from pyeda.logic.addition import kogge_stone_add
>>> A = exprvars('a', 8)
>>> B = exprvars('b', 8)
>>> S, C = kogge_stone_add(A, B)
>>> S.vrestrict({A: "01000000", B: "01000000"})
```

farray([0, 0, 1, 0, 0, 0, 0, 0])

Related Work

It is truly an exciting time for Python in digital logic. There are several available libraries implementing features that are competitive with PyEDA’s.

SymPy was an early influence for PyEDA’s design [Sympy]. It features a logic module that implements symbolic logic expressions. SymPy is implemented in 100% pure Python, and therefore will have some trouble competing with the raw performance of PyEDA’s C extensions.

Another tremendous influence was Ilan Schnell’s pycosat module [Pycosat]. It implements a similar Python interface to the PicoSAT SAT solver [Bie08], but does not delve into the area of symbolic Boolean algebra.

Steve Haynal and others at the University of California Santa Barbara have implemented PyCUDD, a Python binding to the well-known [CUDD] library.

The Sage Math project implements logic and sat modules with similar features to PyEDA’s.

Lastly, there are a few notable Python bindings to other SAT libraries. python-minisat, and pycryptosat implement Python wrappers around MiniSAT and CryptoMiniSAT, respectively. Also, Microsoft recently open sourced the truly excellent Z3 theorem prover library, which has its own SMT SAT solver and Python bindings.
